

# Alternation and Polynomial Time Hierarchy

- **Alternating Turing Machine (ATM)**

An ATM is an NTM with all states, except **accept** and **reject** states, divided into **universal** states and **existential** states.

- $\exists$  node is marked **accept** iff any of its children is marked **accept**.
- $\forall$  node is marked **accept** iff all of its children are marked **accept**.

*Definition 2.1.* An alternating Turing machine (ATM) is a seven-tuple

$$M = (k, Q, \Sigma, \Gamma, \delta, q_0, g),$$

where

$k$  is the number of work tapes,

$Q$  is a finite set of states,

$\Sigma$  is a finite input alphabet ( $\dagger \notin \Sigma$  is an endmarker),

$\Gamma$  is a finite work tape alphabet ( $\# \in \Gamma$  is the blank symbol),

$\delta \subseteq (Q \times \Gamma^k \times (\Sigma \cup \{\dagger\})) \times (Q \times (\Gamma - \{\#\})^k \times \{\text{left, right}\}^{k+1})$  is the next move relation,

$q_0 \in Q$  is the initial state,

$g: Q \rightarrow \{\wedge, \vee, \neg, \text{accept, reject}\}$ .

If  $g(q) = \wedge$  (respectively,  $\vee, \neg, \text{accept, reject}$ ), then  $q$  is said to be a universal (respectively, existential, negating, accepting, rejecting) state.

# Tautology

- $\text{TAUT} = \{ \langle f \rangle \mid f \text{ is a tautology} \}$  (in coNP)

On input  $\langle f \rangle$ :

- Universally select all assignments to the variables of  $f$ .
- For a particular assignment evaluate  $f$
- If  $f$  evaluates to 1 accept, else reject

**MIN-FORMULA** = {  $\langle \phi \rangle$  |  $\phi$  is a minimal Boolean formula, i.e., there is no shorter equivalent }.

(formula is equivalent if they evaluate to same value on assigning the same values to its variables)

**MIN-FORMULA**  $\in$  AP. (not known to be in NP or coNP)

On input  $\phi$  :

1. **Universally** select all formula **f** that are shorter than  $\phi$ .
2. **Existentially** select an assignment to the input variables of  $\phi$ .
3. Evaluate both  $\phi$  and **f** on this assignment.
4. **Accept** if the formulas evaluate to different values; else **reject**.

# EXACT-INDSET

- $\text{INDSET} = \{(G, k) : \text{graph } G \text{ has an independent set of size } k\}$  .
- $\text{EXACT INDSET} = \{(G, k) : \text{the largest independent set in } G \text{ has size exactly } k\}$  .  
 $\text{EXACT INDSET}$  iff *there exists* an independent set of size  $k$  in  $G$  and *every* other independent set has size at most  $k$ .

- It seems that the way to capture such languages is to allow not only an “exists” quantifier (as in Definition of NP) or only a “for all” quantifier (as Definition of coNP) but a combination of both quantifiers. This motivates the following definition:

The class  $\Sigma_2^P$  is defined to be the set of all languages L for which there exists a polynomial-time TM M and a polynomial q such that

- $x \in L$ ,  $\exists u \in \{0, 1\}^{q(|x|)} \forall v \in \{0, 1\}^{q(|x|)}$  such that  $M(x, u, v) = 1 \forall x \in \{0, 1\}^*$ .
- Note that  $\Sigma_2^P$  contains both the classes NP and coNP.

- The language EXACT INDSET above is in  $\Sigma_1^P$  since as we noted above, pair  $(G, k)$  is in EXACT INDSET iff

$\exists S \forall T$ , set  $S$  is an independent set of size  $k$  in  $G$  and  $T$  is not an independent set of size  $k + 1$ .

- The class  $\Pi_2^P$  is defined to be the set of all languages  $L$  for which there exists a polynomial-time TM  $M$  and a polynomial  $q$  such that

$x \in L$  ,  $\forall u \in \{0, 1\}^{q(|x|)} \exists v \in \{0, 1\}^{q(|x|)}$  such that  $M(x, u, v) = 1 \forall x \in \{0, 1\}^*$ .

- **Polynomial Hierarchy:**

Let  $\Sigma_k P$  be a class of language  $L$  accepted by an Alternating Turing Machine that begins in an existential state, alternates between  $\exists$  and  $\forall$  states  $\leq k-1$  times and halts within  $O(T(n))$ .

– Define  $\Sigma_k P = \bigcup_{i=1}^{\infty} \Sigma_k n^i$

The class of complement of languages within  $\Sigma_k P$  is called  $\Pi_k P = \text{co-}\Sigma_k P$ .

$\Pi_k P$ : where ATM begins in a  $\forall$  state.

Note that  $\Sigma_k P \subseteq \Pi_{k+1} P$  and  $\Pi_k P \subseteq \Sigma_{k+1} P$ ,

$\Sigma_1 P = \text{NP}$  and  $\Pi_1 P = \text{co-NP}$ .

**MIN-CIRCUIT** is in  $\Pi_2 P$ .

- Def: The polynomial hierarchy

$$\text{PH} = \sum_k \text{P} = \prod_k \text{P} .$$

- **Alternating Time and Space :**

$ATIME(f(n)) = \{ L : \exists \text{ an ATM that decides } L \text{ in } O(f(n)) \text{ time} \}$

$ASPACE(f(n))$  is defined similarly.

$AL = ASPACE(\log n)$ ,  $AP = ATIME(n^k)$  .

- **Thm:**  $ATIME(f(n)) \subseteq SPACE(f(n)) \subseteq ATIME(f^2(n))$  .

Thus,  $AP = PSPACE$  .

- **Thm:**  $ASPACE(f(n)) = TIME(2^{O(f(n))})$  .  
Thus,  $ASPACE = EXP$  ,  $AL = P$

Lemma: For  $f(n) \geq n$  we have  $ATIME(f(n)) \subseteq SPACE(f(n))$ .

Proof:

Convert an  $O(f(n))$ -time ATM  $M$  to a  $O(f(n))$ -space DTM  $S$ .

$S$  makes a **depth-first search** of  $M$ 's computation tree to determine whether the start configuration is "accept"

or not. It is done by **recursion** and the depth

is  $O(f(n))$ , since the computation tree has depth  $O(f(n))$ .

For each level of recursion, the stack store the non-det choice that  $M$  made to reach that configuration from its parent and this uses only constant space.  $S$  can recover the configuration by "replaying" the computation from the start and following the recorded **"signposts."**

Lemma: Let  $f(n) \geq n$  we have  $\text{SPACE}(f(n)) \subseteq \text{ATIME}(f^2(n))$ .

Proof:

- Let  $M$  be an  $O(f(n))$ -space DTM. We want to construct an  $O(f^2(n))$ -time ATM  $S$  to simulate  $M$ .
- It is very similar to the proof of Savitch's Theorem.  
 $\phi_{c_1, c_2, t} = \exists m [\phi_{c_1, m, t/2} \wedge \phi_{m, c_2, t/2}]$ : indicate if  $C_2$  is reachable from  $C_1$  in  $t$  steps for  $M$ .
- $S$  uses the above recursive alternating procedure to test whether the start configuration can reach an accepting conf. within  $2^{df(n)}$  steps. The recursive depth is  $O(f(n))$ .
- For each level it **takes  $O(f(n))$  time to write a conf.** Thus the algorithm runs in  $O(f^2(n))$  alternating time.

**Lemma:**  $f(n) \geq \log n$  we have  $ASPACE(f(n)) \subseteq TIME(2^{O(f(n))})$ .

Proof:

- Construct a  $2^{O(f(n))}$ -time DTM  $S$  to simulate an  $O(f(n))$ -space ATM  $M$ . On input  $w$ ,  $S$  constructs the following graphs of the computation  $M$  on  $w$ .
- Nodes are conf of  $M$  on  $w$  and edges go from a conf to those configurations that it can yield in a step.
- After the graph is constructed,  $S$  repeatedly scans it and marks certain conf as accepting. **Initially, only actual accepting conf are marked "accepting"**. A conf that performs **universal** branching is marked "accepting" if all its children are marked and an **existential** conf is marked if any of its children are marked.
- $S$  continues until no additional nodes are marked in a scan. **Finally,  $S$  checks if the start conf is marked.** There are  $2^{O(f(n))}$  conf of  $M$  on  $w$ , which is also the size of the graph. Hence the total time used is  $2^{O(f(n))}$ .

Lemma:  $f(n) \geq \log n$  we have  $\text{TIME}(2^{O(f(n))}) \subseteq \text{ASPACE}(f(n))$

Proof:

Construct an  $O(f(n))$ -space ATM  $S$  to simulate a  $2^{O(f(n))}$ -time DTM  $M$ . On input  $w$ ,  $S$  has only enough space to store pointers into a tableau of the computation  $M$  on  $w$  as depicted in the following.

The content of **d** is determined by the contents of its parents **a**, **b**, and **c**.

S **operates recursively** to **guess** and then verify the contents of the individual cells of the tableau. **It is easy to verify the cells of the first row, since it knows the start conf of M on w.**

For other cell  $d$ , **S existentially guesses** the contents of the parents, checks whether their contents would yield  $d$ 's contents according to  $M$ 's transition, and **then universally branches to verify these guesses recursively.**

Assume **M moves its head to the leftmost cell after entering accepting state.** Thus  $S$  can determine whether  $M$  accepts  $w$  by checking the contents of the lower leftmost cell of the tableau. Hence  $S$  never needs to store more than a pointer to a cell in the tableau. So it uses at most  $O(f(n))$  space.
